Certificate in Quantitative Finance

Final Project Brief

June 2023 Cohort

This document outlines topics available for this cohort. No other topics can be submitted. Each topic has by-step instructions to give you a structure (not limit) as to what and how to implement.

Marks earned will strongly depend on your coding of numerical techniques and presentation of how you explored and tested a quantitative model (report in PDF or HTML). Certain numerical methods are too involved or auxiliary to the model, for example, do not recode optimisation or RNs generation. Code adoption allowed if the code fully modified by yourself.

A capstone project requires own study and ability to work with documentation on packages that implement numerical methods in your coding environment e.g., Python, R, Matlab, C#, C++, Java. You do not need to pre-approve the coding language and use of libraries, including very specialised tools such as Scala, kdb+ and q. However, software like EViews is not coding.

Exclusively for current CQF delegates. No distribution.

To complete the project, you must code the model(s) and its numerical techniques form one topic from the below options and write an analytical report. If you continue from a previous cohort, please review topic description because tasks are regularly reviewed. It is not possible to submit past topics.

1. Credit Spread for a Basket Product (CR)
2. Deep Learning for Financial Time Series (DL)
3. Pairs Trading Strategy Design & Back test (TS)
4. Portfolio Construction using Black-Litterman Model and Factors (PC)
5. Optimal Hedging with Advanced Greeks (DH)
6. Blending Ensemble for Classification (ML)

Topics List for the current cohort will be available on the relevant page of Canvass Portal.

Project Report and Submission

- First recommendation: do not submit Python Notebook ' as is' – there is work to be done to transform it into an analytical report. Remove printouts of large tables/output. Write up mathematical sections (with LaTeX markup). Write up analysis and comparison for results and stress-testing (or alike). Explain your plots. Think like a quant about the computational and statistical properties: convergence/accuracy/variance and bias. Make a table of the numerical techniques you coded/utilised.
- Project Report must contain su**ffi**cient mathematical model(s), numerical methods and an adequate conclusion discussing pros and cons, further development.
- There is no set number of pages. Some delegates prefer to present multiple plots on one page for comparability, others choose more narrative style.
- It is optimal to save Python Notebook reports as HTML but do include a PDF with page numbers – for markers to refer to.
- Code must be submitted and working.

FILE 1. For our download and processing scripts to work, it is necessary to name and upload the project report as ONE **fi**le (pdf or html) with the two-letter project code, followed by your name as registered on CQF Portal.
Examples: TS John Smith REPORT.pdf or PC Xiao Wang REPORT.pdf

FILE 2. All other **fi**les, code and a pdf declaration (if not the front page) must be uploaded as additional ONE zip **fi**le, for example TS John Smith CODE.zip. In that zip include converted PDF, Python, and other code **fi**les. Do not submit unzipped .py, .cpp **fi**les as cloud anti-virus likely to **fl**ash red on our side.
Do not submit **fi**les with generic names, such as CODE.zip, FinalProject.zip, Final Project Declaration.pdf, etc. Such **fi**les will be disregarded.

Submission date for the project is Monday 22nd January 2024, 23.59 GMT

There is no extension time to Final Project.

Projects without a hand-signed declaration or working code are incomplete.

Failure to submit ONE report file and ONE zip file according to the naming instructions means such a project will miss an allocation for grading.

All projects are checked for originality. We reserve an option of a viva voce before the qualification to be awarded.

Project Support

Advanced Electives

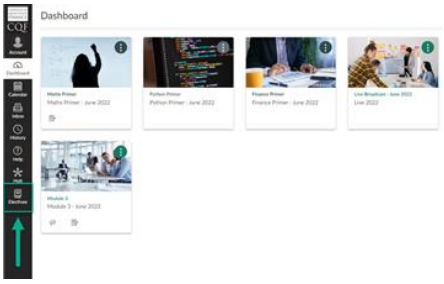
To gain background knowledge in a focused way, we ask you to review two Advanced Electives. Electives canvass knowledge areas and can be reviewed before/at the same time/closer to writing up Analysis and Discussion (explanation of your results).

- There is no immediate match between Project Topics and Electives
- Several workable combinations for each Project Topic are possible
- One elective learning strategy is to select one `topical elective' and one `coding elective'

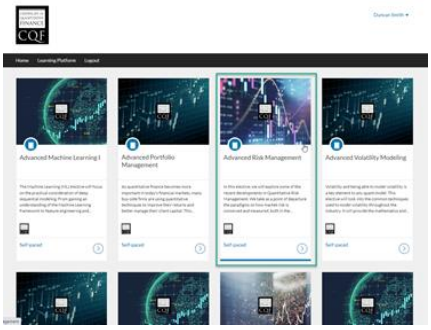
To access the electives:

Login to the CQF Learning Hub

Click the *Learning Platform* button to sign into Canvas

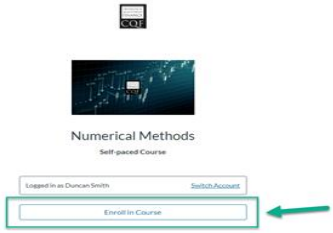


Click on *Electives* button on global navigation menu



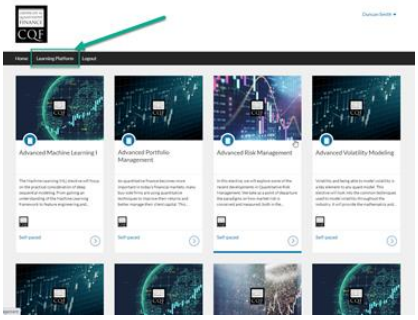
You will be redirected to the electives Catalogue, where you can view and review all electives available to you. Full descriptions for each elective can be found here.

When on an elective click the *enrol* button



You will see the confirmation page, click the *enrol in Course* button to confirm your selection

You will land on the successful enrolment page, where you can click to start the elective or return to the catalogue page



When on the catalogue page you can click the *Learning Platform* link to return to Canvas. Your electives selected will appear on your learning dashboard

Workshop & Tutorials

Each project title is supported by a faculty member alongside a set of project workshops and tutorials.

DATE	TITLE	TIME
02/12/2023	Final Project Workshop I (CR & PC)	13:00 – 15:30 GMT
09/12/2023	Final Project Workshop II (TS, DH, DL & ML)	13:00 – 15:30 GMT
18/12/2023	Final Project Tutorial I (TS & DH Topic)	18:00 – 19:00 GMT
19/12/2023	Final Project Tutorial II (DL & ML Topic)	18:00 – 19:00 GMT
20/12/2023	Final Project Tutorial III (PC Topic)	18:00 – 19:00 GMT
21/12/2023	Final Project Tutorial IV (CR Topic)	18:00 – 19:00 GMT

To ask faulty a question on your chosen topic, please submit a support ticket by clicking on the Support button which can be found in the bottom hand right corner on your portal.

Coding for Quant Finance

- Choose programming environment that has appropriate strengths and facilities to implement the topic (pricing model). Common choice is Python, Java, C++, R, Matlab. Exercise judgement as a quant: which language has libraries to allow you to code faster, validate easier.

- Use of R/Matlab/Mathematica is encouraged. Often there a specific library in Matlab/R gives fast solution for specific models in robust covariance matrix/cointegration analysis tasks.

- Project Brief give links to nice demonstrations in Matlab, and Webex sessions demonstrate Python notebooks {does not mean your project to be based on that ready code

- Python with pandas, matplotlib, sklearn, and tensorow forms a considerable challenge to Matlab, even for visualization. Matlab plots editor is clunky, and it is not that difficult to learn various plots in Python.

- 'Scripted solution' means the ready functionality from toolboxes and libraries is called, but the amount of own coding of numerical methods is minimal or non-existent. This particularly applies to Matlab/R.

- Projects done using Excel spreadsheet functions only are not robust, notoriously slow and do not give understanding of the underlying numerical methods. CQF-supplied Excel spreadsheets are a starting point and help to validate results but coding of numerical techniques/use of industry code libraries is expected.

- The aim of the project is to enable you to code numerical methods and develop model prototypes in a production environment. Spreadsheets-only or scripted solutions are below the expected standard for completion of the project.

- What should I code? Delegates are expected to re-code numerical methods that are central to the model and exercise judgement in identifying them. Balanced use of libraries is at own discretion as a quant.

- Produce a small table in report that lists methods you implemented/adjusted. If using ready functions/borrowed code for a technique, indicate this and describe the limitations of numerical method implemented in that code/standard library.

- It is up to delegates to develop their own test cases, sensibility checks and validation. It is normal to observe irregularities when the model is implemented on real life data. If in doubt, reflect on the issue in the project report.

- The code must be thoroughly tested and well-documented: each function must be described, and comments must be used. Provide instructions on how to run the code.

Credit Spread for a Basket Product

Price a fair spread for a portfolio of CDS for 5 reference names (Basket CDS), as an expectation over the joint distribution of default times. The distribution is unknown analytically and so, co-dependent uniform variables are sampled from a copula and then converted to default times using a marginal term structure of hazard rates (separately for each name). Copula is calibrated by estimating the appropriate default correlation (historical data of CDS differences is natural candidate but poses market noise issue). Initial results are histograms (uniformity checks) and scatter plots (co-dependence checks). Substantial result is sensitivity analysis by repricing.

A successful project will implement sampling from both, Gaussian and t copulae, and price all k-th to default instruments (1st to 5th). Spread convergence can require the low discrepancy sequences (e.g., Halton, Sobol) when sampling. Sensitivity analysis *wrt* inputs is required.

Data Requirements

Two **separate** datasets required, together with matching discounting curve data for each.

1. **A snapshot of credit curves** on a particular day. A debt issuer likely to have a USD/EUR CDS curve – from which a term structure of hazard rates is bootstrapped and utilised to obtain exact default times, $u_i \to \tau_i$. In absence of data, spread values for each tenor can be assumed or stripped visually from the plots in financial media. The typical credit curve is concave (positive slope), monotonically increasing for $1Y, 2Y, \ldots, 5Y$ tenors.

2. **Historical credit spreads time series** taken at the most liquid tenor $5Y$ for each reference name. Therefore, for five names, one computes 5×5 default correlation matrix. Choosing corporate names, it is much easier to compute correlation matrix from equity returns.

   Corporate credit spreads are unlikely to be in open access; they can be obtained from Bloomberg or Reuters terminals (via your firm or a colleague). For sovereign credit spreads, time series of ready bootstrapped PD_{5Y} were available from DB Research, however, the open access varies. Explore data sources such as `www.datagrapple.com` and `www.quandl.com`.

   Even if CDS_{5Y} and PD_{5Y} series are available with daily frequency, the co-movement of daily changes is market noise *more* than correlation of default events, which are rare to observe. Weekly/monthly changes give more appropriate input for default correlation, however that entails using 2-3 years of historical data given that we need at least 100 data points to estimate correlation with the degree of significance.

If access to historical credit spreads poses a problem remember, default correlation matrix can be estimated from historic equity returns or debt yields.

Step-by-Step Instructions

1. For each reference name, bootstrap implied default probabilities from quoted CDS and convert them to a term structure of hazard rates, $\tau \sim Exp(\hat{\lambda}_{1Y}, \ldots, \hat{\lambda}_{5Y})$.

2. Estimate default correlation matrices (near and rank) and d.f. parameter (ie, calibrate copulæ). You will need to implement pricing by Gaussian and t copulæseparately.

3. Using sampling form copula algorithm, repeat the following routine (simulation):

   (a) Generate a vector of correlated uniform random variable.

   (b) For each reference name, use its term structure of hazard rates to calculate exact time of default (or use semi-annual accrual).

   (c) Calculate the discounted values of premium and default legs for every instrument from *1st* to *5th*-to-default. Conduct MC separately or use one big simulated dataset.

4. Average premium and default legs across simulations separately. Calculate the fair spread.

Model Validation

- The fair spread for k*th*-to-default Basket CDS should be less than k-1 to default. Why?

- Project Report on this topic should have a section on **Risk and Sensitivity Analysis** of the fair spread *w.r.t.*

  1. default correlation among reference names: either stress-test by constant high/low correlation or ± percentage change in correlation from the actual estimated levels.
  2. credit quality of each individual name (change in credit spread, credit delta) as well as recovery rate.

  Make sure you discuss and compare sensitivities for all five instruments.

- Ensure that you explain historical sampling of default correlation matrix and copula fit (uniformity of pseudo-samples) – that is, Correlations Experiment and Distribution Fitting Experiment as will be described at the Project Workshop. Use histograms.

Copula, CDF and Tails for Market Risk

The recent practical tutorial on using copula to generate correlated samples is available at:
`https://www.mathworks.com/help/stats/copulas-generate-correlated-samples.html`
Semi-parametric CDF fitting gives us percentile values with fitting the middle and tails. Generalised Pareto Distribution applied to model the tails, while the CDF interior is Gaussian kernel-smoothed. The approach comes from Extreme Value Theory that suggests correction for an Empirical CDF (kernel fitted) because of the tail exceedances.

`http://uk.mathworks.com/help/econ/examples/using-extreme-value-theory-and-copulas-to-evaluate-market-risk.html`

`http://uk.mathworks.com/help/stats/examples/nonparametric-estimates-of-cumulative-distribution-functions-and-their-inverses.html`

Reading List:

- Very likely you will revisit *CDO & Copula Lecture* material, particularly slides 48-52 that illustrate Elliptical copula densities and discuss Cholesky factorisation.
- *Sampling from copula* algorithm is in *relevant Workshop* and *Monte Carlo Methods in Finance* textbook by Peter Jaekel (2002) – see Chapter 5.
- Rank correlation coefficients are introduced *Correlation Sensitivity Lecture* and P. Jaekel (2002) as well. CR Topic Q&A document gives the clarified formulae and explanations.

Deep Learning for Asset Prediction

Summary

Trend prediction has drawn a lot of research for many decades using both statistical and computing approaches including machine learning techniques. Trend prediction is valuable for investment management as accurate prediction could ensure asset managers outperform the market. Trend prediction remains a challenging task due to the semi-strong form of market efficiency, high noise-to-signal ratio, and the multitude of factors that affect asset prices including, but not limited to the stochastic nature of underlying instruments. However, sequential financial time series can be modeled effectively using sequence modeling approaches like a recurrent neural network.

Objective

Your objective is to produce a model to predict positive moves (up trend) using the Long Short-Term Memory Networks. Your proposed solution should be comprehensive with the detailed model architecture, evaluated with a backtest applied to a trading strategy.

- Choose one ticker of your interest from the index, equity, ETF, crypto token, or commodity.
- Predict trend only, for a short-term return (example: daily, 6 hours). Limit prediction to binomial classification: the dependent variable is best labelled [0, 1]. Avoid using [-1, 1] as class labels.
- Analysis should be comprehensive with detailed feature engineering, data pre-processing, model building, and evaluation.

Note: You are free to make study design choices to make the task achievable. You may redefine the task and predict the momentum sign (vs return sign) or direction of volatility. Limit your exploration to ONLY one asset. At each step, the process followed should be expanded and explained in detail. Merely presenting python codes without a proper explanation shall not be accepted. The report should present the study in a detailed manner with a proper conclusion. Code reproducibility is a must and the use of modular programming approaches is recommended. Under this topic, you do not recode existing indicators, libraries, or optimization to compute neural network weights and biases.

Step-by-Step Instructions

1. The problem statement should be explicitly specified without any ambiguity including the selection of underlying assets, datasets, timeframe, and frequency of data used.

- If predicting short-term return signs (for the daily move), then training and testing over up to 5 years should be sufficient. If you attempt the prediction of 5D, 10D return for equity or 1W, 1M for the Fama French factor, you'll have to increase the data required to at least 10 years.

2. Perform exhaustive Feature Engineering (FE).

- FE should be detailed including the listing of derived features and specification of the target/label. Devise your approach on how to categorize extremely small near-zero returns (drop from the training sample or group with positive/negative returns). The threshold will strongly depend on your ticker. Example: small positive returns below 0.25% can be labelled as negative.
- Class imbalances should be addressed - either through model parameters or via label definition.
- Use of features from cointegrated pairs and across assets is permitted but should be tactical about design. There is no one recommended set of features for all assets; however, the initial feature set should be sufficiently large. Financial ratios, advanced technical indicators including volatility estimators, and volume information can be a predictor for price direction.
- OPTIONAL Use of news heatmap, credit spreads (CDS), historical data for financial ratios, history of dividends, purchases/disposals by key stakeholders (director dealings) or by large funds, or Fama-French factor data can enhance your prediction and can be sourced from your professional subscription.

3. Conduct a detailed Exploratory Data Analysis (EDA).

- EDA helps in dimensionality reduction via a better understanding of relationships between features and uncovers underlying structure, and invites detection/explanation of the outliers. The choice of feature scaling techniques should be determined by EDA.

4. Proper handling of data is a must. The use of a different set of features, lookback length, and datasets warrant cleaning and/or imputation.

5. Feature transformation should be applied based on EDA.

- Multi-collinearity analysis should be performed among predictors.
- Multi-scatter plots presenting relationships among features are always a good idea.
- Large feature sets (including repeated kinds, and different lookbacks) warrant a reduction in dimensionality in features. Self Organizing Maps (SOM), K-Means clustering, or other methods can be used for dimensionality reduction. Avoid using Principal Component Analysis (PCA) for non-linear datasets/predictors.

6. Perform extensive and exhaustive model building.

- Design the neural network architecture after extensive and exhaustive study.
- The best model should be presented only after performing the hyperparameter optimization and compared with the baseline model.
- The choice and number of hyperparameters to be optimized for the best model are design choices. Use experiment trackers like MLFlow or TensorBoard to present your study.

7. The performance of your proposed classifier should be evaluated using multiple metrics including backtesting of the predicted signal applied to a trading strategy.

- Investigate the prediction quality using AUC, confusion matrix, and classification report including balanced accuracy (if required).
- Predicted signals should be evaluated by applying them to a trading strategy.

* * *

Pairs Trading Strategy Design & Backtest

Cointegrated relationship between prices gives way to arbitrage. The arb is based on the mean-reversion of a stationary spread, which is a special cointegrated residual. Put signal generation and backtest at the centre of project, it's not about one-off run of statistical routines. Conventionally, pairs trading is done via correlation, and you can still check a range of assets for high correlation in search of pairs. However, pairs trading with 100% -100% weights is naive doesn't account for dollar difference and is not conductive to the stationarity of residual. Asset prices must be tied in using cointegration (error-correction model) because they are non-stationary series, $I(1)$ leading to the assumption that Integrated Brownian Motion is an underlying process. Suitability of the spread for trading depends on OU process fitting and half-life.

The numerical techniques to implement: matrix form autoregression, Engle-Granger procedure, and statistical tests. You are encouraged to venture into multivariate cointegration (VECM, Johansen procedure) and robustness checking of cointegration weights, ie, by adaptive estimation of your regression parameters (optionally). The advantage of multivariate cointegration: weights of your trading strategy will be difficult to guess from the outside. That comes however with the loss of $P\&L$ attribution (explanation), beta dev level Python libraries (to year 2023). In comparison, Engle-Granger procedure is very affine and controllable, therefore a good choice to start cointegration analysis. It is for pairwise analysis of two series only.

Signal Generation and Backtesting

- Be inventive beyond equity pairs: consider commodity futures, VIX futures, US/UK bonds ETFs and other instruments on interest rates.
- Arb is realised by using cointegrating coefficients $\boldsymbol{\beta}_{Coint}$ as allocations $\boldsymbol{w}$. That creates a long-short portfolio that generates a mean-reverting spread. All project designs should include trading signal generation (from OU process fitting) and backtesting (drowdown plots, rolling SR, rolling betas).
- Does cumulative P&L behave as expected for a cointegration arb trade? Is P&L coming from a few or many trades, what is half-life? Maximum Drawdown and behaviour of volatility/VaR?
- Introduce liquidity and algorithmic flow considerations (a model of order flow). Any rules on accumulating the position? What impact bid-ask spread and transaction costs will make?

Step-by-Step Instructions

Can utilise the ready multivariate cointegration (R package *urca*) to identify your cointegrated cases first, especially if you operate with the system such as four commodity futures (of different expiry but for the period when all traded. 2-3 pairs if analysing separate pairs by EG.

Part I: Pairs Trade Design

1. Even if you work with pairs, re-code regression estimation in matrix form – your own OLS implementation which you can re-use. Regression between stationary variables (such as DF test regression/difference equations) has OPTIONAL model specification tests for (a) identifying optimal lag p with AIC BIC tests and (b) stability check.

2. Implement Engle-Granger procedure for each your pair. For Step 1 use Augmented DF test for unit root with lag 1. For Step 2, formulate both correction equations and decide which one is more significant.

3. Decide signals: common approach is to enter on bounds $\mu_e \pm Z\sigma_{eq}$ and exit on e_t everting to about the level μ_e.

4. At first, assume $Z = 1$. Then change Z slightly upwards and downwards – compute P&L for each case of widened and tightened bounds that give you a signal. Alternatively run an optimisation that varies Z_{opt} for $\mu_e \pm Z_{opt}\sigma_{eq}$ and either maximises the cumulative P&L or another criterion.
   Caution of the trade-off: wider bounds might give you the highest P&L and lowest N_{trades} however, consider the risk of co-integration breaking apart.

5. OPTIONALLY attempt multivariate cointegration with R package *urca* – as of 2023 Python VECM models are only available in Github dev versions of *statsapi* – in order select the best candidates for pairs/basket trading.

Part II: Backtesting

It is your choice as a quant to decide which elements you need to present on the viability, robustness and 'uncorrelated returns' nature of your trading strategy.

4. Think of machine learning-inspired backtesting, such as splitting data into train/test subsets, preprocessing, and crossvalidaiton as appropriate and feasible (beware of crossvalidation issues with time series analysis).

5. Perform systematic backtesting of your trading strategy (returns from a pairs trade): produce drawdown plots, rolling Sharpe Ratio, at least one rolling beta *wrt* to the S&P500 excess returns. However discuss why rolling beta(s) might not be as relevant to stat arb and market-making.

6. OPTIONALLY Academic research will test for breakouts in cointegrated relationship with LR test. Cointegrated relationship supposed to persist and β'_{Coint} should stay the same: continue delivering the stationary spread over 3-6 months without the need to be updated. Is this realistic for your pair(s)?
   Discuss benefits and disadvantages of regular re-estimation of cointegrated relationships by shifting data 1-2 weeks (remember to reserve some future data), and report not only on rolling β'_{Coint}, but also Engle-Granger Step 2, the history of value of test statistic for the coefficient in front of EC term.
   Would you implement something like Kalman filter/particle filter adaptive estimation [applied to cointegrated regression] in order to see the updated β'_{Coint} and μ_e? Reference: `www.thealgoengineer.com/2014/online_linear_regression_kalman_filter/`.

TS Project Workshop, Cointegration Lecture and Pairs Trading tutorial are your key resources.

Portfolio Construction using Black-Litterman Model and Factors

Summary

Construct a factor-bearing portfolio, compute at least two kinds of optimisation. Within each optimisation, utilise the Black-Litterman model to update allocations with absolute and relative views. Compute optimal allocations for three common levels of risk aversion (Trustee/Market/Kelly Investor). Implement systematic backtesting: which includes both, regressing results of your portfolio on factors and study of the factors themselves (wrt the market excess returns).

Kinds of optimisation: mean-variance, Max Sharpe Ratio, higher-order moments (min coskewness, max cokurtosis) – implement at least two. Min Tracking Error also possible but for that your portfolio choice will be measured against a benchmark index. Computation by ready formula or specialised for quadratic programming. Adding constraints improves robustness: most investors have margin constraints / limited ability to borrow / no short positions.

OPTIONALLY, Risk Contributions can also computed *ex ante* for any optimal allocation, whereas computing ERC Portfolio requires solving a system of risk budget equations (non-linear). ERC computation is not an optimisation, however can be 'converted' into one – sequential quadratic programming (SQP).

Portfolio Choice and Data

The choice of portfolio assets must reflect optimal diversification. The optimality depends on the criterion. For the max possible decorrelation among assets, it is straightforward to choose the least correlated assets. For exposure/tilts to factor(s) – you need to know factor betas *a priori*, and include assets with either high or low beta, depending on purpose.

A naive portfolio of S&P500 large caps is fully exposed to one factor, the market index itself, which is not sufficient. Specialised portfolio for an industry, emerging market, credit assets should have 5+ names, and > 3 uncorrelated assets, such as commodity, VIX, bonds, credit, real estate.

Factor portfolio is more of a long/short strategy, e.g., momentum factor means going long top 5 raising stocks and short top 5 falling. Factor portfolios imply rebalancing (time diversification) by design.

- mean-variance optimisation was specified by Harry Markowitz for simple returns (not log) which are *in excess* of the r_f. For risk-free rate, 3M US Treasury from pandas FRED dataset/ECB website rates for EUR/some small constant rate/zero rate – all are acceptable. Use 2-3 year sample, which means > 500 daily returns.
- Source for prices data is Yahoo!Finance (US equities and ETFs). Use code libraries to access that, Google Finance, Quandl, Bloomberg, Reuters and others. If benchmark index not available, equilibrium weights computed from the market cap (dollar value).
- In this variation of PC topic, it is necessary to introduce 2-3 factor time series and treat them as investable assets (5 Fama-French factors). If using Smart Beta ETFs present on their structure – you might find there is no actual long/short factors, just a long-only collection of assets with particularly high betas.

Step-by-Step Instructions

Part I: Factor Data and Study(Backtesting)

1. Implement Portfolio Choice based on your approach to optimal diversification. Usually the main task is to select a few assets that gives risk-adjusted returns the same as/outperforms a much larger, naturally diversified benchmark such as S&P500. See Q&A document distributed at the Workshop.
2. Experiment which factors you are going to introduce, collect their time series data or compute.
    - The classic Fama-French factors are HML (value factor) and SMB (small business). RMW (robust vs. weak profitability) and CMA (conservative vs aggressive capex) are the new factors and you can experiment with them.
    - Exposure to sector or style can also be considered a factor.
    - It very recommended that you introduce an interesting, custom factor such as Momentum, BAB (betting against beta) – likely you will need to compute time series of its returns, however that can be as simple as returns from a short portfolio of top five tech stocks.
3. The range of portfolios, for which factors are backtested, is better explained at source `http://mba.tuck.dartmouth.edu/pages/faculty/ken.french/data_library.html`
4. Present P&L returns and Systematic Backtesting of your factors vs the Market (index of your choice), which includes performance, present plots of rolling beta and changing alpha. Ideally, you can present results for each factor beta independently and then, in combination. This work to be presented even before you engage in portfolio optimisation

Part II: Comparative Analysis of BL outputs

1. Plan your Black-Litterman application. Find a ready benchmark or construct the prior: equilibrium returns can come from a broad-enough market index. Implement computational version of BL formulae for the posterior returns.
2. Imposing too many views will make seeing impact of each individual view difficult.
3. Describe analytically and compute optimisation of **at least two kinds**. Optimisation is improved by using sensible constraints, eg, budget constraint, 'no short positions in bonds' but such inequality constraints $\forall w_i > 0$ trigger numerical computation of allocations. e.
4. You will end up with multiple sets of optimal allocations, even for a classic mean-variance optimisation (your one of two kinds). Please make your own selection on which results to focus your Analysis and Discussion – the most feasible and illustrative comparisons.
    - Optimal allocations (your) vs benchmark for active risk. Expected returns (naïve) vs implied equilibrium returns (alike to Table 6 in BL Guide by T. Idzorek.)
    - BL views are not affected by covariance matrix – therefore, to compute allocations shifted by views (through Black-Litterman model) with naive or robust covariance is your choice.

- Three levels of risk aversion – it is recommended that you explore at least for classical Min Var optimisation.

5. There is no rebalancing task for the project, particularly because posterior BL allocations expected to be durable.
6. Compare performance of your custom portfolio vs factors and market (rolling beta), independently and jointly. OPTIONALLY, compare performance of your portfolio to $1/N$ allocations / Diversification Ratio portfolio / Naive Risk Parity kind of portfolio and perform the systematic backtesting of that portfolio *wrt* to factors.

Reading List

- CQF Lecture on Fundamentals of Optimization and Application to Portfolio Selection
- A Step-by-step Guide to The Black-Litterman Model by Thomas Idzorek, 2002 tells the basics of what you need to implement.
- The Black-Litterman Approach: Original Model and Extensions Attilio Meucci, 2010. http://ssrn.com/abstract=1117574
- On LW nonlinear shrinkage / Marcenko-Pastur denoising, either method to make a covariance matrix robust, resources and certain code provided with the relevant Workshop and Tutorial.

Optimal Hedging with Advanced Delta Modelling

Summary

In this topic, you first consider the simple volatility arbitrage under condition of future realised volatility being above the implied, $V_a > V_i$. The workings can be found in Understanding Volatility lecture solutions. Implement in code the delta replication: long option, short stock. Use European call option Black-Scholes formulae, high/low volatility values of your choice. Provide visibility into how Gamma affects the P&L over Δt. GBM evolution should utilise its numerical techniques and advanced Monte-Carlo with variance reduction and/or ready low discrepancy sequences. Not necessary to consider a portfolio of options or several assets.

Improvement in delta-hedging can be achieved by adjusting the naive Black-Scholes Delta. We choose Minimum Variance Delta approach which corrects delta with the expected change in σ_{imp} as a result of change in asset S_t,which is $\frac{\partial E(\sigma_{imp})}{\partial S}$. The underlying idea is simple: anticipate the magnitude of change in implied volatility and adjust Black-Scholes Delta for it.

MVD model coefficients a, b, c estimation can be done via a regression on $\delta_{BS}, \delta_{BS}^2$ as independent variables directly, for which you re-arrange $\Delta V - \delta_{BS}\Delta S$ into dependent variable. More advanced method would be sequential least square programming optimiser (scipy) to solve for a, b, c as parameters that minimise $\sum \epsilon_{MV}^2$, the hedging error defined in Hull and White (2017).

In your findings on MVD you are likely to make, illustrate and discuss the following discoveries. (1) You are likely to discover the MVD to be consistently less than BS Delta and therefore, naive delta-hedging typically overhedges. That is particularly effective for out-of-the-money call options. (2) After estimation, it can be uncovered that difference MV Delta - BS Delta ($\delta_{MV} - \delta_{BS}$) gives an inverted parabola-like function empirically (across delta buckets), and therefore quadratic fitting recipe arises. (3) The advanced implementation will consider the Gain function, defined as the percentage reduction in the sum of the squared residuals resulting from the hedge.

IV Options Data

1. S&P500 index options data is available from brokerages and data providers **OptionsDX.com**, Polygon.io. OptionsDX is a particularly good current choice (2023) that provides some free End Of Day (EOD) option quotes. For each trading day, and each expiry/strike, you will need BS option price as implied vol percentage, delta, and vega: $(V, \delta_{BS}, \nu_{BS})_t$.

2. In the absence of historical options data, implied volatility values can be randomly generated from a **uniform** distribution from a range of values. To simulated values, apply a multiplicative factor that varies from short to long expiry. That recipe mimics IV patterns observed in equity index options, and can be adapted with your own knowledge of how smile transpires in markets you work with.

3. This project does not require fitted volatility surfaces or Bloomberg/front-desk level option price data but you can certainly use volatility data from any source.

Step-by-Step Instructions

Part I: Volatility Arb with improved GBM and Monte-Carlo

1. Consider improvements to GBM asset evolution (Euler-Maruyana/Milstein schemes). Optionally, can consider modelling asset with jumps, eg, Merton jump diffusion, without going into stochastic volatility, eg Heston-Nandi. Variance Gamma is also relevant but suited for single-name assets with extreme movements.
    - consider MC variance reduction techniques, such as antithetic variates;
    - best practice is low discrepancy sequences, eg Sobol with the Brownian bridge.
2. Under the condition of known future realised volatility $V_a > V_i$, analytically and with Monte-Carlo confirm the items below. Report with both, complete mathematical workings to fold $P\&L_t$ and simulations of $P\&L_t$.
    - confirm *actual* volatility hedging leads to the known total P&L;
    - confirm and demonstrate *implied* volatility hedging leads to uncertain total, path-dependent P&L, and characterise on which parameters/Greeks it depends.
3. Think of additional analysis: consider how P&L decomposes in terms of Greeks. What is the impact of time-dependent Gamma Γ_t? What about $r^2 - \sigma_{imp}\delta t$? Consider findings from Part II MVD modelling, what are the implications of hedging with the smaller delta?

Part II: Minimum Variance Delta

1. begin with sorting your IV data – or each trading day, you will need BS option price as implied vol percentage, delta, and vega: $(V_t, \delta_{BS}, \nu_{BS})$. The term structure for option expiry $1M, 3M, 6M, 9M, 12M$, weekly expiries not necessary. Key choice to make here, if you are going to study Delta for out of the money call strikes, in addition to about ATM buckets $0.45 < \delta_{BS} < 0.55$ – each strike means a separate a, b, c history for each expiry.
2. compute your dependent variable and run the fitting on $\delta_{BS}, \delta_{BS}^2$. Dependent side based on daily option price *changes* ΔV_t, and you will need $(\Delta S_t, S_t)$ as well as Greeks noted above. The exact data columns will depend on how you organise regression or do SLSQP.
3. parameters a, b, c can be constant for a study project, but rolling estimation itself is a calibration technique because for each expiry, you have time-dependent a,b,c (not 3 constants). Hull White recipe was 3M rolling window, then shift the start date by one day (3×22 obs) – you can estimate with shorter/longer periods or shift by $5 - 10$ days. Also remember, option IVs can be simulated from a uniform distribution recipe.
4. For model validation, look at change of a, b, c over time – we use regression as a fitting tool so they might not even be statistically significant. Check if $\delta_{MV} - \delta_{BS}$ gives an (inverted) parabolic shape, plot expected change in IV vs Delta.
5. $\mathbb{E}[\Delta\sigma_{imp}]$ expected to be negative but might not be. Is your achieved hedging Gain anywhere close to 15% and in which delta buckets and expiries?

Additional Material – a small, curated collection of relevant articles will be distributed at Project Workshop (I or II). Volatility-related core lectures from Module 3 also support this Topic DH.

Blending Ensemble for Classification

Summary

Trend prediction is valuable for investment management as accurate prediction could ensure asset managers outperform the market. Trend predictions can be modeled effectively using machine learning algorithms; however, the choice of learning techniques to be adopted remains a challenging task. Ensemble learning is a powerful machine learning algorithm that combines the predictions of multiple machine learning models by mitigating the errors or biases that may exist in individual models by leveraging the collective intelligence of multiple models that leads to a more precise prediction.

Objective

Your objective is to produce a model to predict positive moves (up trend) using the Blending Ensemble technique. Your proposed solution should be comprehensive with the detailed model architecture, evaluated with a backtest applied to a trading strategy.

- Choose one ticker of your interest from the index, equity, ETF, crypto token, or commodity.
- Predict trend only, for a short-term return (example: daily, 6 hours). Limit prediction to binomial classification: the dependent variable is best labelled [0, 1]. Avoid using [-1, 1] as class labels.
- Analysis should be comprehensive with detailed feature engineering, data pre-processing, model building, and evaluation.
- Use only machine learning algorithms for this project.

Note: You are free to make study design choices to make the task achievable. You may redefine the task and predict the momentum sign (vs return sign) or direction of volatility. Limit your exploration to ONLY one asset. At each step, the process followed should be expanded and explained in detail. Merely presenting python codes without a proper explanation shall not be accepted. The report should present the study in a detailed manner with a proper conclusion. Code reproducibility is a must and the use of modular programming approaches is recommended. Under this topic, you do not recode existing indicators, libraries, or optimization algorithms.

Step-by-Step Instructions

1. The problem statement should be explicitly specified without any ambiguity including the selection of underlying assets, datasets, timeframe, and frequency of data used.

- If predicting short-term return signs (for the daily move), then training and testing over up to 5 years should be sufficient. If you attempt the prediction of 5D, 10D return for equity or 1W, 1M for the Fama French factor, you'll have to increase the data required to at least 10 years.

2. Perform exhaustive Feature Engineering (FE).

- FE should be detailed including the listing of derived features and specification of the target/label. Devise your approach on how to categorize extremely small near-zero returns (drop from the training sample or group with positive/negative returns). The threshold will strongly depend on your ticker. Example: small positive returns below 0.25
- Class imbalances should be addressed - either through model parameters or via label definition.
- Use of features from cointegrated pairs and across assets is permitted but should be tactical about design. There is no one recommended set of features for all assets; however, the initial feature set should be sufficiently large. Financial ratios, advanced technical indicators including volatility estimators, and volume information can be a predictor for price direction.
- OPTIONAL Use of news heatmap, credit spreads (CDS), historical data for financial ratios, history of dividends, purchases/disposals by key stakeholders (director dealings) or by large funds, or Fama-French factor data can enhance your prediction and can be sourced from your professional subscription.

3. Conduct a detailed Exploratory Data Analysis (EDA).

- EDA helps in dimensionality reduction via a better understanding of relationships between features and uncovers underlying structure, and invites detection/explanation of the outliers. The choice of feature scaling techniques should be determined by EDA.

4. Proper handling of data is a must. The use of a different set of features, lookback length, and datasets warrant cleaning and/or imputation.

5. Feature transformation should be applied based on EDA.

- Multi-collinearity analysis should be performed among predictors.
- Multi-scatter plots presenting relationships among features are always a good idea.
- Large feature sets (including repeated kinds, and different lookbacks) warrant a reduction in dimensionality in features. Self Organizing Maps (SOM), K-Means clustering, or other methods can be used for dimensionality reduction. Avoid using Principal Component Analysis (PCA) for non-linear datasets/predictors.

6. Perform extensive and exhaustive model building.

- The architecture of a stacking model should involve at least three base learners.
- Hyperparameters of each base learners should be optimized.
- Type of base learners and meta model to be used are design choices.

7. The performance of your proposed classifier should be evaluated using multiple metrics including back-testing of the predicted signal applied to a trading strategy.

- Investigate the prediction quality using AUC, confusion matrix, and classification report including balanced accuracy.
- Predicted signals should be evaluated by applying them to a trading strategy.

Reading List for Final Project (Selected Topics)

The puprpose of this list is not to provide textbooks, but rather more specific chapters and sample articles, from which you will gain topic knowledge/key model knowledge. The readings identified below and additional curated titles will be released with Project Workshops and/or Project Tutorials in files named *Topic XX - Additional Material.zip*.

Reading List: Credit Portfolio

- Very likely you will revisit *CDO & Copula Lecture* material, particularly slides 48-52 that illustrate Elliptical copula densities and discuss Cholesky factorisation.
- *Sampling from copula* algorithm is in *relevant Workshop* and *Monte Carlo Methods in Finance* textbook by Peter Jaekel (2002) – see Chapter 5.
- Rank correlation coefficients are introduced *Correlation Sensitivity Lecture* and P. Jaekel (2002) as well. CR Topic Q&A document gives the clarified formulae and explanations.

Reading List: Portfolio Construction

- CQF Lecture on *Fundamentals of Optimization and Application to Portfolio Selection*
- *A Step-by-step Guide to The Black-Litterman Model* by Thomas Idzorek, 2002 tells the basics of what you need to implement.
- *The Black-Litterman Approach: Original Model and Extensions* Attilio Meucci, 2010. `http://ssrn.com/abstract=1117574`
- Marcenko-Pastur denoising / LW nonlinear shrinkage became optional. Either method aims to make the covariance matrix such that mean-variance optimisaiton is less perturbed by the degree of noise. Resources can be provided with the relevant FP Workshop/Tutorial.

Reading List: Cointegrated Pairs

- *Modeling Financial Time Series*, E. Zivot & J. Wang, 2002 – we distribute Chapter 12 on Cointegration with the relevant Project Workshop (concerns with terms inside error-correction equation).
- Instead of a long econometrics textbook, read up *Explaining Cointegration Analysis: Parts I and II* by David Hendry and Katarina Juselius, 2000 and 2001. *Energy Journal*.
- Appendices of this work explain key econometric and OU process maths links, *Learning and Trusting Cointegration in Statistical Arbitrage* by Richard Diamond, *WILMOTT* `papers.ssrn.com/sol3/papers.cfm?abstract_id=2220092`.

Reading List: Delta Hedging and Local Volatility

- *Optimal Delta Hedging for Options* by John Hull & Alan White. *Journal of Banking and Finance*, Vol. 82, Sept 2017 (available on SSRN and distributed with Project Workshop). Previous version 2016.
- *Manufacturing and Managing Customer-Driven Derivatives* textbook by Dong Qu – we distribute Chapter 12 (pp. 319-331) for the Local Volatility in Rates model specifically.
- *Lecture 7: Local Volatility Continued* by Emmanuel Derman (2008) lectures on Volatility Smile, which we still find useful. Local Volatility in general can be read about in any good textbook.
- *Advanced Volatility Modelling* comes either as Elective or Alumni Workshop in CQF Lifelong Library (but it might concern with jump-diffusion and stochastic volatility).

Reading List: Deep Learning and Ensemble Learning

- *Short-term stock market price trend prediction using a comprehensive deep learning system* by Jingyi Shen and M. Omair Shafiq, Journal of Big Data volume 7, (2020).
- *A graph-based CNN-LSTM stock price prediction algorithm with leading indicators* by Jimmy Ming-Tai Wu et al. (2021).
- *A comprehensive evaluation of ensemble learning for stock-market prediction* by Isaac Kofi Nti, Journal of Big Data volume 7, (2020).
- *A Blending Ensemble Learning Model for Crude Oil Price Prediction* by Mahmudul Hasan et al. (2022). `papers.ssrn.com/sol3/papers.cfm?abstract_id=4153206`.
- *Advanced Machine Learning I & II* comes either as Elective or Alumni Workshop in CQF Lifelong Library.
